A B S T R A C T

The rare earth elements and yttrium (REY) are enriched in marine sedimentary phosphorites, which are an important REY resource. The formation of marine REY-rich phosphorites is a product of sedimentary deposition, while some geochemical studies of phosphorites suggest that they also have the characteristics of hydrothermal deposition. Hydrothermal modification can have an important effect on the distribution of REY and REY minerals in phosphorites, although there is no direct mineralogical evidence for such hydrothermal activity. In this study, we used transmission electron microscopy and other microbeam techniques to investigate the hydrothermal activity during the formation of marine sedimentary phosphorites in the early Cambrian Gezhongwu Formation, Zhijin, South China. Geochemical and mineralogical evidence shows that late hydrothermal events occurred after formation of the marine sedimentary phosphorites. The observed micro-scale hydrothermal veins (e.g., barite), micro- and nano-scale hydrothermal minerals (e.g., anatase and fluorite), and hydrothermally transformed minerals (e.g., fluorapatite and zircon) provide direct mineralogical evidence of later hydrothermal activity. The hydrothermal fluid involved in the phosphorite deposition might have been a low-temperature reduced fluid, which was enriched in F, Ti. Moreover, the late hydrothermal activity changed the REY patterns of some minerals (e.g., fluorapatite and zircon) in the phosphorites, although the hydrothermal activity was not the main factor that controlled REY enrichment in the phosphorites. Our results not only provide direct evidence for hydrothermal transformation of marine sedimentary phosphorites, but also a possible explanation for the bell-shaped rare earth element patterns in apatite, suggesting that the apatite would not provide a reliable reconstruction of the paleo-ocean environmental conditions.

1. Introduction

The global demand for rare earth elements (REEs) and yttrium (i.e., REY), which are critical for emerging technologies such as in the electronics industry and renewable energy resources, is increasing rapidly (Service, 2010; Chen et al., 2011; Kato et al., 2011; Chakhmouradian and Wall, 2012). More than 85% of the world's REY supply comes from two types of deposit in China (Kynicky et al., 2012; Xu et al., 2017). The first is in alkaline igneous and carbonatitic rocks (e.g., the Bayan Obo deposit in China, which supplies 80% of the light rare earth elements

worldwide; Orris and Grauch, 2002; Kynicky et al., 2012), and the other type is regolith-hosted ion adsorption deposits in southern China, which supply much of the heavy rare earth elements worldwide (Bao and Zhao, 2008; Xu et al., 2017).

It is necessary to identify other economic REY-rich deposits to meet the rapidly increasing REY demand (Long et al., 2010). Marine sedimentary phosphate deposits enriched in extractable REY could represent a new type of REY deposit in the future (Emsbo et al., 2015; Peiravi et al., 2021). Such deposits are rich in middle and heavy REEs.

The origin of such a REY-rich phosphorite deposit in the early

Cambrian Gezhongwu Formation in China remains unclear. Previous studies (Emsbo et al., 2015; Fan et al., 2016; Chen et al., 2019) have shown that REY-rich phosphorites in the Gezhongwu Formation are of marine sedimentary origin. However, some studies have suggested that this deposit has characteristics typical of hydrothermal deposition, based on trace elements and fluid inclusions (Wang et al., 2004; Shi, 2005; Guo et al., 2017; Liu et al., 2019), although there is no direct evidence for hydrothermal activity. Submarine hydrothermal activity might be an important factor in REY enrichment, as such fluids are rich in REY (Michard et al., 1983; Han et al., 2017). Furthermore, hydrothermal activity can transform protogenetic minerals (Harlov, 2015; Li and Zhou, 2015; Liu et al., 2019) and effect REY distribution in phosphorites.

Mineral grains in some marine sedimentary phosphorites are relatively small (micro- or nano-scale) and difficult to study. Transmission electron microscopy (TEM) can reveal the structure and chemical composition of minerals at the nano-scale (Li and Zhou, 2015; Lee et al., 2016; Liao et al., 2019). In this study, we used a combination of TEM and other microbeam techniques to investigate phosphorites in the early Cambrian Gezhongwu Formation, Zhijin, South China. We identified several lines of mineralogical evidence for hydrothermal activity, such as barite veins, nano-anatase, micro- and nano-scale fluorite inclusions in dolomite, altered microcrystalline detrital zircon, and hydrothermally transformed fluorapatite. In order to determine the effects of the hydrothermal fluids on the incorporation of REY into the phosphorites, we compared the REY concentrations and patterns of hydrothermally transformed fluorapatite (Type II) with those of francolite without obvious hydrothermal modification (Type I). We also examined the effects of the hydrothermal fluids on microcrystalline zircon using TEM. Our results show that the late hydrothermal activity might have been caused by a low-temperature reduced fluid, which strongly modified the REY distribution in the phosphorites.

2. Geological setting

2.1. Sedimentary history

The early Cambrian was an important period of phosphorite formation. During this time, phosphorites in the Gezhongwu Formation were deposited in a transgressive setting following the regression in the late Sinian. These rocks were deposited at shallow-water ramp in the Yangtze platform (Pu et al., 1993; Chen et al., 2013; Fig. 1), and comprise dolomite, phosphate, and siliceous rocks. The largest phosphate deposit in China was formed in the early Cambrian, which was caused by the transgression and upwelling ocean currents. Previous studies have shown that the sedimentary facies include an old land–littoral tidal flat–shallow-water ramp (phosphate-bearing carbonate ramp), a deep-water ramp (phosphatic concretion-bearing siliceous ramp), and continental slope deep-water basin from southwest to east (Chen et al., 2013; Zhou et al., 2019; Fig. 1). When the Zhijin area began to undergo subsidence during the early Cambrian, the extensive transgression formed an open sea platform facies. The phosphorites of the Gezhongwu Formation in the Zhijin area were deposited in a shallow-water ramp setting (Pu et al., 1993; Chen et al., 2013; Fig. 1).

2.2. Deposit geology

The Zhijin phosphorite deposits in the early Cambrian Gezhongwu Formation are located in the southwestern "Central Guizhou Uplift". The deposits are located in the Guohua anticline and are NE–SW-trending (Mao et al., 2015; Fig. 2). The Gezhongwu Formation is dominated by alternating dolomitic bioclastic phosphorite and phosphatic dolostone. The contact between the Gezhongwu Formation and the underlying Maolongjing section of the Dengying Formation is an unconformity. The upper section of Gezhongwu Formation are siliceous phosphorites, which are overlain by the lower section of the Niutitang Formation. (Wei

et al., 2018; Chen et al., 2019; Zhou et al., 2019).

The Re–Os isotopic age of the black shale at the base of the Niutitang Formation in the Zhijin area is 522.9 ± 8.6 Ma, which constrains the latest age for the Gezhongwu Formation (Wei et al., 2018). In contrast, the best estimate of the age of the Gezhongwu Formation is 535.2 ± 1.7 Ma (Zhu et al., 2009). The Gezhongwu Formation in Guizhou and the Zhujiaqing Formation in Yunnan are correlative (Yang et al., 2005), so that deposition of the Gezhongwu Formation might have occurred between 535.2 ± 1.7 and 522.9 ± 8.6 Ma.

The phosphatic rocks are relatively low grade in P_2O_5 content, with an average content of 16–20 wt%, but contain abundant REEs and particularly high Y contents (approximately 35% of total REEs). The Y-group REEs comprise 45%–59% of the total REEs (Chen et al., 2013). The rare earth oxide (RE_2O_3) grade of the ore is 0.0541–0.1527 wt%, with an average of 0.1036 wt%. The Y_2O_3 grade is 0.0161–0.0583 wt%, with an average of 0.0371 wt% (Meng et al., 2015). In the Zhijin area, a total of 3.5 million tons RE_2O_3 resources of REY-rich phosphorites in the Gezhongwu Formation in early Cambrian have been identified (Guo et al., 2017).

3. Samples and analytical techniques

A total of 20 samples were collected and analyzed from the early Cambrian Gezhongwu Formation phosphorites (Fig. 2). The samples collected in five different areas were labeled GZW, MTC, ZK2001, ZK2002, and ZK2504. Based on major elements, the samples were divided into four types: phosphate–cemented phosphorites, dolomitic phosphorites, phosphorous–bearing dolomites, and siliceous phosphorites. All samples were made into 0.1 mm thick–sections for quantitative elemental analysis and mapping.

3.1. Whole-rock major elements

The rock powders were first heated to 900 °C for 90 min to remove organics and carbonates. Approximately 0.50 g of each pre-heated sample was then mixed with 4.00 g of $Li_2B_4O_7$, and the mixture was fused at 1200 °C and cooled to make a glass disc. Major elements were analyzed using a Rigaku ZSX100e X-ray fluorescence spectrometer. The analytical precision was $<\pm1\%$ (relative standard deviation; RSD).

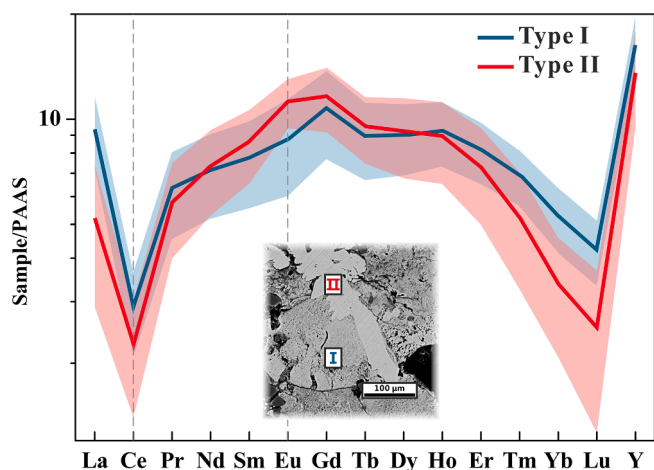

Fig. 4. Post-Archean Australian Shale (PAAS; Taylor, 1985)-normalized REY patterns for Type I and II fluorapatite, with SEM–BSE photomicrographs. Blue and red lines are the averages of Type I and II fluorapatite, respectively. The shaded area is the 95% confidence interval.

3.2. Whole-rock trace elements

Sample powders were heated to 550 °C for 3 h to eliminate organic material. Approximately 40.0 mg of each sample was then digested and analyzed using a Thermo Icap Qc inductively coupled plasma mass spectrometer (ICP–MS; Wang et al., 2018). Rhodium was added to each sample as an internal standard. The analytical precision was $< \pm 3\%$ (relative standard deviation; RSD).

3.3. In situ major element analyses

For the *in situ* major element analyses, thin-sections were polished using diamond powder. The analyses were conducted with a JEOL JXA-8230 electron probe microanalyzer (EPMA) at the Key Laboratory of Mineralogy and Metallogeny (KLMM) in the Guangzhou Institute of Geochemistry (GIG), Chinese Academy of Sciences (CAS), Guangzhou, China. The analyses were carried out using a beam size of 4 μm, a 20nA beam current, and a 15 kV accelerating voltage. Peak and background counting times were 60, 30, 20, 10, 10, and 5 s for Si, S, Ca, P, F, and Cl, respectively. The Kα line was used for the analyses. Fluorine and chlorine were first analyzed during the analytical routine in order to minimize volatile loss. The data were reduced using the ZAF correction method. The standards used were as follows: francolite for Ca and P, BaF_2 for F, tugtupite for Cl, diopside for Si, and pyrite for S. The relative precisions were $\pm 2\%$ for Ca, P, and F, and $\pm 5\%$ for Si, Cl, and S (Xing and Wang, 2017).

3.4. In situ trace element analyses

Trace elements were analyzed by laser ablation (LA)–ICP–MS at the KLMM in the GIG, CAS. A Resonetics 193 nm ArF excimer LA system (GeoLasPro) was used for laser sampling, and the ion signal intensities were measured using an Agilent 7500a ICP–MS. The laser conditions were as follows: 29 μm laser spot size, 80 mJ laser energy, and 6 Hz laser frequency. Helium was used as a carrier gas. Each analysis consisted of a 20 s background measurement (laser off) followed by 45 s of data acquisition (laser on). The external standard was NIST SRM 610, and NIST SRM 612 was analyzed as quality control. The Ca content of francolite determined by EPMA was used as an internal standard. Data processing was undertaken using the ICPMSDataCal software (version 10.2; Liu et al., 2008).

3.5. Scanning electron microscopy

Thin-sections of rock samples were prepared for scanning electron microscopy (SEM) observations using a Phenom XL SEM equipped with a back-scattered electron (BSE) detector and an energy dispersive spectrometer (EDS), with a 15 kV accelerating voltage and 20nA beam current at the KLMM in the GIG, CAS.

3.6. Transmission electron microscopy

Thin-sections for TEM observations, with a thickness of approximately 100 nm, were prepared using a focused ion beam (FIB) and a FEI Scios dual beam system at the Institute of Geochemistry, CAS. The TEM observations were conducted using an FEI Talos F200S microscope operated at 200 kV at the KLMM in the GIG, CAS. Various techniques, including scanning TEM (STEM), high-resolution TEM (HRTEM), selected area electron diffraction (SAED), and energy dispersive spectroscopy (EDS), were used for morphological, structural, and compositional investigations.

4. Results

4.1. Major and trace element features of the phosphorite

Major and trace element data are listed in Tables 1 and 2, respectively. Based on geochemical features, the samples were divided into four lithological types, including phosphate-cemented phosphorite, dolomitic phosphorite, phosphorous-bearing dolomite, and siliceous phosphorite. The phosphate-cemented phosphorites contain 31.40–37.70 wt% P_2O_5, 49.30–52.90 wt% CaO, 0.11–3.77 wt% MgO, and 1.39–4.37 wt% SiO_2. The dolomitic phosphorites contain 12.40–29.70 wt% P_2O_5, 37.20–48.30 wt% CaO, 4.09–13.40 wt% MgO, and 0.66–3.96 wt% SiO_2. The phosphorous-bearing dolomites contain 3.20–9.51 wt% P_2O_5, 28.00–34.20 wt% CaO, 12.80–17.65 wt% MgO, and 1.02–10.86 wt% SiO_2. The siliceous phosphorites contain 20.10–23.30 wt% P_2O_5, 32.20–35.80 wt% CaO, 1.09–5.60 wt% MgO, and 16.61–25.02 wt% SiO_2. The Fe/Ti ratios vary from 10.67 to 153.00, with an average of 41.70. Compared with crustal abundances (Taylor, 1985), the phosphorites are relatively enriched in Ni, Sr, Pb, U, As, Mo, Sb, and Zn, and are relatively depleted in Cr, Th, Zr, Rb, and V (Table 2). The U/Th ratios range from 0.74 to 7.95 (average = 3.16), and only one sample has U/Th < 1.

4.2. REY geochemistry of the phosphates

The REY concentrations in 20 samples of the Zhijin phosphates range from 210 to 1716 ppm, with an average of 996 ppm (Table 3). The Ce anomaly (δCe) and Eu anomaly (δEu) were calculated as: $\delta Ce = Ce_N / \sqrt{La_N \times Pr_N}$; $\delta Eu = Eu_N / \sqrt{Sm_N \times Gd_N}$ (where the subscript N denotes normalization to Post-Archean Australian Shale [PAAS] values; e. g., $Ce_N = Ce_{sample}/Ce_{PAAS}$; Taylor, 1985). The δCe values are all < 0.5, with $\delta Ce_{average} = 0.37$. The δEu values of 15 samples are > 1, whereas those of the other samples are approximately 1 (average = 1.06).

4.3. Hydrothermally transformed fluorapatite

Both the phosphate-cemented and dolomitic phosphorites consist of fluorapatite grains. The REY elements are mainly concentrated in the fluorapatite of phosphorite (Jarvis et al., 1994; Fleet and Pan, 1995; Emsbo et al., 2015; Hughes and Rakovan, 2015). The SEM–BSE photomicrographs of fluorapatite grains show two types of morphologies with different contrast (Fig. 3a–f). Type I fluorapatite is autogenetic francolite, which is a mixture consisting mainly of nano-fluorapatite (50–200 nm; Fig. 3g–i), with biofossil shapes or detrital features that also appear "dirty" and relatively dark in the photomicrographs. Type II fluorapatite
Fig. 5. SEM–BSE photomicrographs of hydrothermal veins in phosphorous-cemented phosphates. BHV = black hydrothermal vein; Brt = barite; F-Ap = fluorapatite; Zrn = zircon; Fe oxide = iron oxide; Ilt = Illite.

consists of hydrothermally transformed grains (10–50 μm), which appear "clean" and bright in SEM–BSE photomicrographs (Fig. 3a–f). From the relationship between Type I and Type II (Fig. 3c), it can be seen that Type II probably formed by fluid-aided dissolution-reprecitation from Type I. EMPA maps show that Type II fluorapatite contained higher contents of Ca, P and F (Fig. 6a–d). It is worth noting that Type II flu-orapatite is mainly distributed around the black hydrothermal vein (BHV) (Fig. 6b). LA–ICP–MS analyses of the two types of fluorapatite (Table 4) show that the total REY concentrations of the two types are in the sequence of Type I > Type II. The PAAS-normalized REY patterns of the two types are shown in Fig. 4. The Ce and Eu anomaly diagram of the two types of fluorapatite (Fig. 14b) shows that from type I to type II, negative Ce anomaly change from 0.31 to 0.35 on average and Eu anomaly change from 0.95 (no positive anomaly) to 1.16 (positive anomaly) on average.

4.4. Ore petrography

Several fissure-filled barite and mixed minerals veins were observed in the phosphate samples by SEM–BSE imaging (Fig. 5). The chemical compositions of the veins were further constrained by EPMA elemental mapping (Fig. 6), which showed that Al, Ba, Si, and Fe are enriched in the BHVs, while Ba and S are enriched in the barite veins. The mineral phases in the veins were identified from Raman spectra and μ-XRD patterns. The results show that the barite veins consist mainly of a pure barite phase (Fig. 7). Given that the size of the mineral grains in the BHVs were too small to be identified by either Raman or μ-XRD methods, TEM techniques with FIB sampling were used to identify the mineral phases. The BHVs consist mainly of illite, goethite, nano-scale anatase, and microcrystalline zircon (Fig. 8). Hydrothermally transformed fluo-rapatite occurs near the BHVs (Fig. 6b).

In the BHVs, numerous microcrystalline detrital zircons (<10 μm) were observed by SEM (Fig. 9). The fine structure of the zircons was examined by FIB–TEM. The altered zircon (Fig. 10c) has the same crystal
Fig. 6. EPMA elemental maps of phosphates in the barite and mixed-mineral veins. The numbered points (1–7) marked in (a) are sites where micro-Raman spectra were acquired. I and II in (b) denote autogenetic francolite and hydrothermally transformed fluorapatite, respectively.

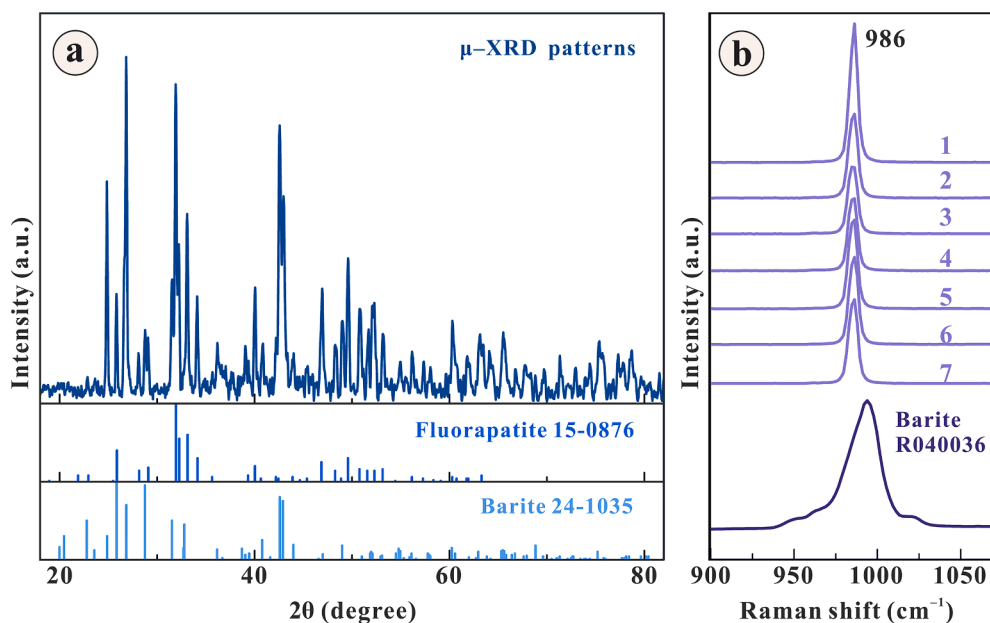

Fig. 7. (a) μ-XRD patterns of the blue zone marked in Fig. 5b and (b) Raman spectra for the barite veins. The spectra numbers correspond to those marked in Fig. 6a.

orientation as the unaltered zircon (Fig. 10d). The EDS maps showed that Y, Ti, Fe, and Al are higher in concentration in the altered zircons than in the unaltered zircon cores.

Numerous micro- and nano-scale fluorite inclusions are evenly distributed in dolomite in the dolomitic phosphorite (Fig. 11). The

abundance of F-bearing micro-mineral inclusions were determined by SEM–EDS mapping (Fig. 11a–i). The mineral phases were further identified by TEM–SAED analyses (Fig. 11j–l). In addition, abundant pores were observed in the dolomites in SEM images.

5. Discussion

5.1. Later hydrothermal alteration of the phosphorites

Based on major and trace element features of whole-rock, the Zhijin phosphorites probably experienced hydrothermal alteration. Immobile elements such as Fe, Mn, and Ti can be used to identify hydrothermal activity. Fe/Ti ratio can also be used to investigate the hydrothermal history of geological units (Boström, 1983). The average Fe/Ti ratios of the investigated samples is 41.70 (Table 1), which is higher than the threshold value of 20, indicating that the samples might be affected by hydrothermal activities. An Fe–Mn–(Cu + Ni + Co) × 10 ternary diagram can be used to identify the hydrothermal activity (Fig. 12). Most data plots in the hydrothermal deposition zone, which suggests the sedimentary phosphorites have experienced hydrothermal alteration.

Trace element data for the whole-rock samples can also be used to identify the origin. The U/Th ratio is commonly used for this, as the Th concentration is higher than that of U in most sedimentary rocks, as compared with other types of rocks. Therefore, U/Th > 1 indicates a hydrothermal deposition, whereas U/Th < 1 indicates a sedimentary origin (Rona, 1978). The U/Th ratios of the phosphorites are 0.74–7.95, with an average of 3.16, indicative of hydrothermal activity. Enrichments of certain trace elements can also be used as an indicator of hydrothermal deposition (Marchig et al., 1982; Boström, 1983). The enrichment factors (i.e., normalized to the trace element abundances of the upper crust) of As and Sb in the samples are 24.9 and 67.5, respectively, indicating that the phosphorites are hydrothermal in nature. Furthermore, the presence of hydrothermal micro- and nano-scale minerals (barite, anatase, and fluorite; Figs. 5 and 8) and hydrothermally altered fluorapatite and zircon (Figs. 3 and 8) provide direct evidence of later hydrothermal activity.

5.2. The nature of hydrothermal fluids

The chemical composition and redox state of hydrothermal fluids are key factors in controlling the process of hydrothermal alteration. Fluorapatite is the main constituent mineral in the studied phosphorites, and thus the relative elemental enrichment of hydrothermally transformed fluorapatite might reflect the chemistry of the hydrothermal fluids. PAAS-normalized REY patterns can reveal the sedimentary paleoenvironmental conditions (Grandjean et al., 1987; Ilyin, 1998; Jiedong et al., 1999), thus the REY patterns of the marine sedimentary francolite (Type I) (Fig. 4) can be used to disclose sedimentary paleoenvironmental conditions. The REY patterns of marine sedimentary francolites (Type I) exhibit marked negative Ce anomalies, no Eu anomalies, enrichment of middle REEs, and obvious enrichment in Y (Fig. 4). The negative Ce anomalies might indicate oxidized depositional conditions (Wright et al., 1987; Holser, 1997). In addition, Ce depletion and obvious

enrichment in Y are the characteristics of seawater, which probably indicate that the REY of type I francolites from seawater. The hydrothermally transformed fluorapatite (Type II) has both negative Ce and positive Eu anomalies, indicating that the Eu anomalies were probably caused by the later hydrothermal transformation (Table 4; Fig. 4) (Michard et al., 1983; Mitra et al., 1994). The Ce and Eu anomaly diagram of the two types of fluorapatite (Table 4; Fig. 14b) shows that Ce anomalies and Eu anomalies are changed obviously from type I to type II. The change (from 0.31 to 0.35 on average; Table 4) of Ce anomaly indicates that the degree of oxidation was weakened, which may be caused by reduced fluid activity. The change (from 0.95-no positive to 1.16-positive) of Eu anomaly may also because of reduced fluid activity (Michard et al., 1983; Mitra et al., 1994). The positive Eu anomaly is characteristic of reduced hydrothermal fluids rather than oxidized (Yi et al., 1995). Since the formation environment of the type II fluorapatite was still an oxidizing environment, a large amount of Eu^{2+} in the hydrothermal fluid was oxidized to Eu^{3+}, which entered the type II fluorapatite lattice, so the PAAS-normalized REY patterns of type II fluorapatite are positive Eu anomalies. The REY patterns of whole-rock exhibit marked negative Ce anomalies, positive Eu anomalies, enrichment of middle REEs, and obvious enrichment in Y (Fig. 13). Therefore, the phosphorites probably formed in an oxidizing environment, and were then modified by a reduced fluid.

The nano-scale anatase observed in the BHVs (Figs. 5 and 8) indicates that the hydrothermal fluid was saturated with Ti. Titanium is prone to forming F-containing acid-based coordination complexes in F-bearing fluids, which can then cause large-scale migration of Ti (Collins et al., 1982; Rapp et al., 2010), even though it is one of the most immobile high-field-strength elements in nature. The enrichment of F in the hydrothermal fluid is further evident from the abundant micro- and nano-scale fluorite inclusions (Fig. 11). Therefore, the hydrothermal fluid was rich in both F and Ti. Altered microcrystalline detrital zircon is a good evidence of later hydrothermal fluid alteration. The STEM EDS mapping images show that the relative enrichment of high field strength elements, such as Y, U and Ti (Fig. 10h–l), in the altered edges of the zircon, which indicate that zircon was probably altered by F-rich hydrothermal fluid. The similar crystallographic orientation of the unaltered zircon cores and altered edges (Fig. 10c,d) indicates that the zircon was altered *in situ*.

The temperature of a hydrothermal fluid is another important parameter in understanding the origins of ore deposits. Firstly, anatase generally crystallizes at low temperatures and pressures (Doucet, 1967). Therefore, the large amount of nano-anatase in the BHVs might have formed from relatively low-temperature hydrothermal fluids. Secondly, hydrothermal barite, is generally formed in the low-temperature stage of mineralization (Yang et al., 2008; Zhang et al., 2020), which is an evidence of low-temperature hydrothermal activity in phosphorites. This temperature range is consistent with estimates from fluid inclusions

(87.5–127.8 °C and 99.8–184.3 °C; Liu et al., 2019).

In summary, our mineralogical and *in situ* elemental analyses suggest that the hydrothermal fluid involved in the phosphorite deposition was a low-temperature reduced fluid, which was enriched in F, Ti.

5.3. Influence of hydrothermal activity on the phosphorites

Based on our results, the REY-rich phosphorites in the early Cambrian Gezhongwu Formation might have formed during normal marine sedimentation stage and later hydrothermal alteration stage. This produced the complex geochemical and mineralogical features in the phosphorites. The type I francolite is detrital formed during normal marine sedimentation stage, whereas the type II fluorapatite and other low-temperature hydrothermal minerals formed during hydrothermal activity stage.

The type I francolite might have had a biological origin or be an authigenic deposit. For biogenic francolite, adsorption of dissolved REY ions from seawater would be the dominant process that concentrates the REY elements, as the REY substitute in the Ca sites (Jarvis et al., 1994; Piper, 1999; Liao et al., 2019; Lumiste et al., 2019). The formation of authigenic francolite was an important sedimentary sink for reactive P in the oceans, and authigenic francolite is an important part of marine sedimentary phosphorite deposits (Ruttenberg and Berner, 1993; Schenau et al., 2000). The phosphate that formed the authigenic francolite originated by microbial degradation of organic matter, desorption from Fe oxides, and dissolution of marine faunal debris (Suess, 1981; Frohlich et al., 1983; Ruttenberg and Berner, 1993; Slomp et al., 1996). The REY are incorporated into the apatite lattice during the formation of francolite and/or absorption from seawater after its formation. The origin of the REY from seawater explains the similar initial REY contents and patterns of the biogenic and authigenic francolite.

Later hydrothermal activity was also important in controlling the formation of the REY-rich phosphorites, which changed the REY patterns of minerals such as fluorapatite and zircon. Hydrothermally transformed fluorapatite (Type II) formed from authigenic francolite (Type I) due to the effects of hydrothermal fluids. The REY substitute for Ca in the apatite lattice (Hughes et al., 1991; Fleet and Pan, 1997). The hydrothermal transformation resulted in the Type II fluorapatite being depleted in light and heavy REEs, and slightly enriched in the middle REEs (Table 4; Figs. 4 and 14). This may because the ionic radius of middle REE^{3+} are more suitable for the two Ca^{2+} sites in the apatite structure and have higher apatite/melt partition coefficients (Reynard et al., 1999; Hughes and Rakovan, 2015). Therefore, the transformation resulted in the loss of light and heavy REEs and formation of a positive Eu anomaly. As such, we speculate that F-rich hydrothermal

Fig. 14. (a) REY patterns and REY ratios of Type II fluorapatite divided by those of Type I francolite. The line is the average REY data, and the shaded area is the 95% confidence interval. (b) Ce and Eu anomaly diagram of the two types of fluorapatite.

transformation may be one reason for the bell-shaped REE patterns of apatite. Such apatite may not be a suitable proxy for paleo-ocean environmental reconstructions.

In summary, the later hydrothermal activity changed the REY patterns of various minerals in the phosphorites and the distribution of REY in the phosphorites. However, the hydrothermal activity was not the main reason for the REY enrichment in the phosphorites.

6. Conclusions

The REY-rich phosphorites in the early Cambrian Gezhongwu Formation formed by both normal marine sedimentation and hydrothermal deposition. The phosphorites formed in two stages. The first stage was the normal marine sedimentation stage, during which authigenic francolite (Type I) formed. The second stage was the low-temperature hydrothermal transformation stage, which hydrothermally transformed fluorapatite (Type II), altered zircon, and formed other hydrothermal minerals (e.g., barite, anatase, and fluorite).

In situ geochemical data and mineralogical evidence allowed the properties of the hydrothermal fluids involved in the Gezhongwu Formation phosphorite deposits to be determined. The hydrothermal fluids were low-temperature and reduced. In addition, the hydrothermal fluids might have been relatively rich in F, Ti.

The low-temperature reduced hydrothermal fluid changed the distribution of REY in the phosphorites and the REY patterns of minerals. The hydrothermally transformed fluorapatites are enriched in middle REEs, and depleted in light and heavy REEs. The hydrothermal fluid was not the main factor responsible for the REY enrichment. We speculate that F-rich hydrothermal activity could be one of the reasons for the bell-shaped REE patterns in apatite. Therefore, such REY signals of apatite should pay careful attention to paleo-ocean environmental reconstructions.
